

CS396: Security, Privacy & Society

Fall 2022

Lecture 7: Cryptographic System I

Instructor: Abrar Alrumayh

September 19, 2022

Announcements

CS396: Teaching assistants

- ◆ Teaching assistants (across all 5 sections)
 - ◆ Yogita Bugade (ybugade@stevens.edu) , Leonel Trubbo (ltrubbo@stevens.edu),
Jared Weinblatt jweinbla@stevens.edu), Mihir Joshi (mjoshi14@stevens.edu),
Rajat Shetty (rshett2@stevens.edu), Gil Gerard Austria (gaustralia@stevens.edu),
Devharsh Trivedi (dtrived5@stevens.edu), Samaneh
Berenjian (sberenji@stevens.edu)
 - ◆ assistance w/ labs, assignments, “help sessions” as needed, some grading, demos
 - ◆ Office hours: TBA

Outline

- ◆ Introduction to modern cryptography
 - ◆ Introduction to modern cryptography
 - ◆ Computational security
 - ◆ Pseudo-randomness – stream ciphers/PRGs, block ciphers/PRFs, DES Vs. AES
 - ◆ Modes of operations

Introduction to modern cryptography

Cryptography / cryptology

- ◆ Etymology
 - ◆ two parts: “crypto” + “graphy” / “logy”
 - ◆ English translation: secret + write / speech, logic
 - ◆ meaning: secret writing / the study of secrets
- ◆ Historically developed/studied for secrecy in communications
 - ◆ message encryption in the symmetric-key setting
 - ◆ main application area: use by military and governments

Classical Vs. modern cryptography

antiquity – ~70s

*“the **art of writing and solving codes**”*

- ◆ approach
 - ◆ ad-hoc design
 - ◆ trial & error methods
 - ◆ empirically evaluated

~80s – today

*“the study of **mathematical techniques** for **securing** information, systems, and distributed computations against **adversarial attacks**”*

- ◆ approach
 - ◆ systematic design & analysis
 - ◆ formal notions of security (or adversary)
 - ◆ rigorous proofs of security (or insecurity)

Example: Classical Vs. modern cryptography for encryption

antiquity – ~70s

*“the **art of writing and solving codes**”*

- ◆ **ad-hoc study**

- ◆ vulnerabilities/insecurity of
 - ◆ Caesar's cipher
 - ◆ shift cipher
 - ◆ mono-alphabetic substitution cipher
 - ◆ Vigenère cipher

~80s – today

*“the study of **mathematical techniques** for **securing** information, systems, and distributed computations against **adversarial attacks**”*

- ◆ **rigorous study**

- ◆ **problem statement:** secret communication over insecure channel
- ◆ **abstract solution concept:** symmetric encryption, Kerckhoff's principle, perfect secrecy
- ◆ **concrete solution & analysis:** OTP cipher, proof of security

Example: Differences of specific ciphers

Caesar's/shift/mono-alphabetic cipher

- ◆ substitution ciphers
 - ◆ Caesar's cipher
 - ◆ **shift is always 3**
 - ◆ shift cipher
 - ◆ **shift is unknown and the same for all characters**
 - ◆ mono-alphabetic substitution/Vigènere cipher
 - ◆ **shift is unknown and the same for all/many character occurrences**

The one-time pad

- ◆ also, a substitution cipher
 - ◆ **shift is unknown and independent for each character occurrence**

Formal treatment in modern cryptography

Problem is formulated as an abstract crypto primitive

- ◆ captures the essence of the problem at hand, provides clarity and focus

Design & evaluation of crypto primitives follows a systematic process

- ◆ (A) **formal definitions** (what it means for a crypto primitive to be secure?)
- ◆ (B) **precise assumptions** (which forms of attacks are allowed – and which aren't?)
- ◆ (C) **provable security** (why a candidate solution is secure – or not?)

(A) Formal definitions

abstract but rigorous description of security problem

- ◆ **computing setting** (to be considered)
 - ◆ involved parties, communication model, core functionality
- ◆ **underlying cryptographic scheme** (to be designed)
 - ◆ e.g., symmetric-key encryption scheme
- ◆ **desired properties** (to be achieved)
 - ◆ security related
 - ◆ non-security related
 - ◆ e.g., correctness, efficiency, etc.

(A) Why formal definitions are important?

- ◆ **successful project management**
 - ◆ good design requires clear/specific security goals
 - ◆ helps to avoid critical omissions or over engineering
- ◆ **provable security**
 - ◆ rigorous evaluation requires a security definition
 - ◆ helps to separate secure from insecure solutions
- ◆ **qualitative analysis/modular design**
 - ◆ thorough comparison requires an exact reference
 - ◆ helps to secure complex computing systems

Example: Problem at hand

abstract but rigorous description of **security problem** (to be solved)

secret communication

Insecure channel

Example: Formal definitions (1)

- ◆ computing setting (to be considered)

- ◆ e.g., involved parties, communication model, core functionality

Alice, Bob, Eve

Alice wants to send a message m to Bob; Eve can eavesdrop sent messages

Alice/Bob may transform the transmitted/received message and share info

Alice m

Bob

Example: Formal definitions (2)

- ◆ **underlying cryptographic scheme** (to be designed)

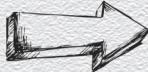

→ symmetric-key encryption scheme

- ◆ Alice and Bob share and use a key k
- ◆ Alice encrypts plaintext m to ciphertext c and sends c instead of m
- ◆ Bob decrypts received c to get a message m'

Example: Formal definitions (3)

- ◆ **desired properties** (to be achieved)

- ◆ **security (informal)**  Eve “cannot learn” m (from c)

- ◆ **correctness (informal)**

-  If Alice encrypts m to c , then Bob decrypts c to (the original message) m

Example: Formal definitions (4)

Perfect correctness

- for any $k \in \mathcal{K}$, $m \in \mathcal{M}$ and any ciphertext c output of $\text{Enc}_k(m)$, it holds that

$$\Pr[\text{Dec}_k(c) = m] = 1$$

Perfect security (or information-theoretic security)

- the adversary should be able to learn no additional information on m

random experiment
 $\mathcal{D}_{\mathcal{M}} \rightarrow m$

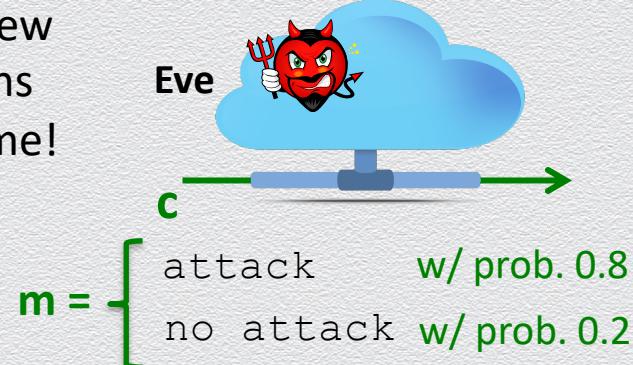

$\mathcal{D}_{\mathcal{K}} \rightarrow k$

$\text{Enc}_k(m) \rightarrow c$

$$m = \begin{cases} \text{attack} & \text{w/ prob. 0.8} \\ \text{no attack} & \text{w/ prob. 0.2} \end{cases}$$

17

(B) Precise assumptions

precise description of all relevant problem components

- ◆ **adversary / attacker**
 - ◆ type of attacks – a.k.a. **threat model**
 - ◆ **capabilities** (e.g., a priori knowledge, access to information, party corruptions)
 - ◆ **limitations** (e.g., bounded memory, passive Vs. active)
- ◆ **computational assumptions** (about hardness of certain tasks)
 - ◆ e.g., factoring of large composite numbers is hard
- ◆ **computing setting**
 - ◆ system set up, initial state, key distribution, randomness...
 - ◆ means of communication (e.g., channels, rounds, ...)
 - ◆ timing assumptions (e.g., synchronicity, epochs, ...)

(B) Why precise assumptions are important?

- ◆ **basis** for proofs of security
 - ◆ security holds under specific assumptions
- ◆ **comparison** among possible solutions
 - ◆ relations among different assumptions
 - ◆ stronger/weaker (i.e., less/more plausible to hold), “A implies B” or “A and B are equivalent”
 - ◆ refutable Vs. non-refutable
- ◆ **flexibility** (in design & analysis)
 - ◆ **validation** – to gain confidence or refute
 - ◆ **modularity** – to choose among concrete schemes that satisfy the same assumptions
 - ◆ **characterization** – to identify simplest/minimal/necessary assumptions

Example: Precise assumptions (1)

- ◆ **adversary**

- ◆ type of attacks – a.k.a. **threat model** → eavesdropping
- ◆ **capabilities** (e.g., a priori knowledge, access to information, party corruptions)
- ◆ **limitations** (e.g., bounded memory, passive Vs. active)

→ Eve may know the a priori distribution of messages sent by Alice

→ Eve doesn't know/learn the secret k (shared by Alice and Bob)

Example: Precise assumptions (2)

- ◆ **computational assumptions** (about hardness of certain tasks)
 - ◆ e.g., factoring of large composite numbers is hard

no computational assumptions
– a.k.a. perfect secrecy (or information-theoretic security)

Example: Precise assumptions (3)

- ◆ **computing setting**
 - ◆ **system set up**, initial state, **key distribution**, **randomness**... → key k is generated randomly using the uniform distribution
 - ◆ means of **communication** (e.g., channels, rounds, messages...)
 - ◆ timing assumptions (e.g., synchronicity, epochs, ...)

→ key k is securely distributed to and securely stored at Alice and Bob

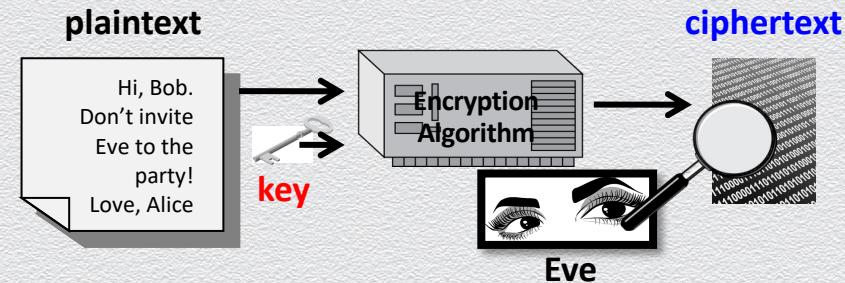

→ one message m is only communicated
(for simplicity in our initial security definition) → k, m are chosen independently

Possible eavesdropping attacks (I)

An attacker may possess a

- ◆ collection of ciphertexts
 - ◆ ciphertext only attack (or simply EAV)

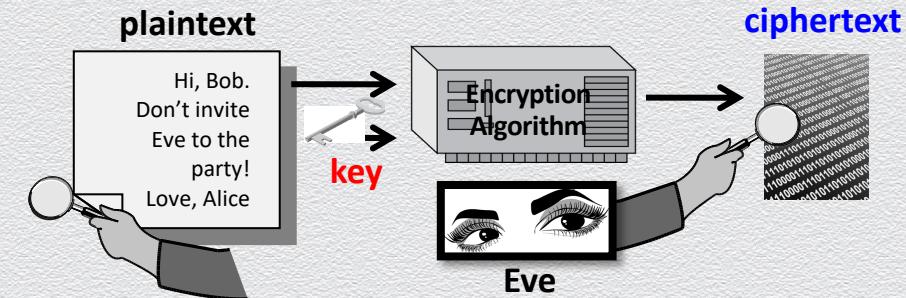

Plain thread model

Possible eavesdropping attacks (II)

An attacker may possess a

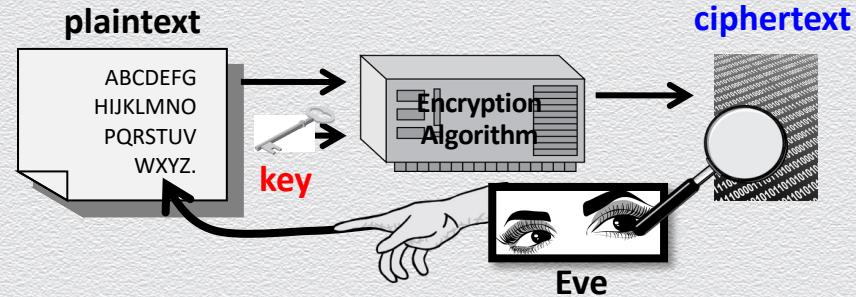

- ◆ collection of plaintext/ciphertext pairs
 - ◆ known plaintext attack

Possible eavesdropping attacks (III)

An attacker may possess a

- ◆ collection of plaintext/ciphertext pairs for plaintexts selected by the attacker
 - ◆ chosen plaintext attack (CPA)

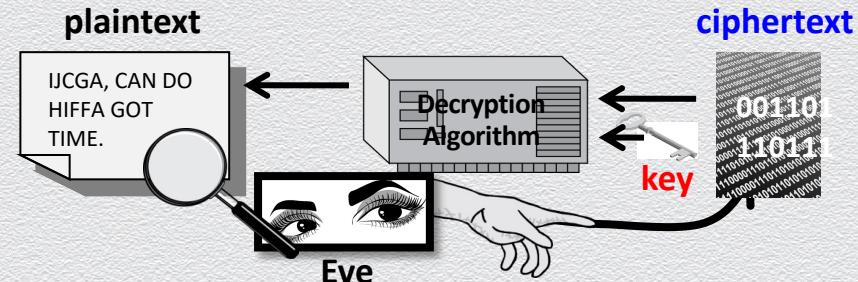

Advanced threat model

Possible eavesdropping attacks (IV)

An attacker may possess a

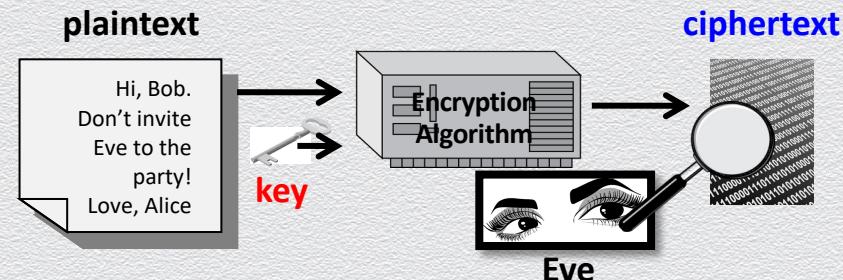

- ◆ collection of plaintext/ciphertext pairs for ciphertexts selected by the attacker
 - ◆ chosen ciphertext attack (CCA)

Main security properties against eavesdropping

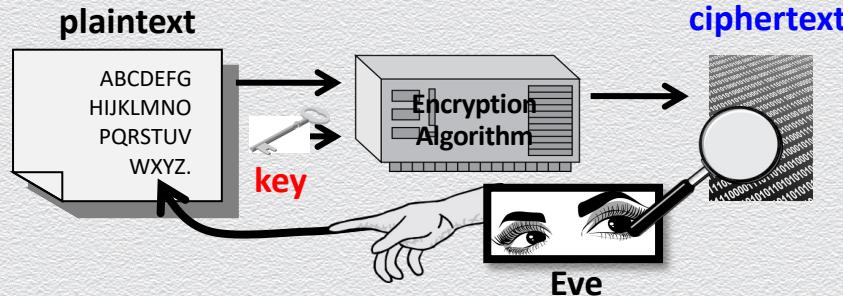

“plain” security

- ◆ protects against ciphertext-only attacks

“advanced” security

- ◆ protects against chosen plaintext attacks

(C) Provably security

Security

- ◆ subject to certain **assumptions**, a scheme is proved to be **secure** according to a specific **definition**, against a specific **adversary**
 - ◆ in practice the scheme may break if
 - ◆ some assumptions do not hold or the attacker is more powerful

Insecurity

- ◆ a scheme is proved to be **insecure** with respect to a specific **definition**
 - ◆ it suffices to find a **counterexample attack**

(C) Why provable security is important?

Typical performance

- ◆ in some areas of computer science **formal proofs may not be essential**
- ◆ behavior of hard-to-analyze algorithms is simulated to experimentally study their performance on “typical” inputs
- ◆ in practice, **typical/average case** occurs

Worst case performance

- ◆ in cryptography and secure protocol design **formal proofs are essential**
 - ◆ “experimental” security analysis is not possible
 - ◆ the notion of a “typical” adversary makes little sense and is unrealistic
- ◆ in practice, **worst case attacks will occur**
 - ◆ an adversary will use any means in its power to break a scheme

Computational security

The big picture: OTP is perfect but impractical!

We formally defined and constructed the perfectly secure OTP cipher

- ◆ This scheme has some major drawbacks
 - ◆ it employs a very large key which can be used only once!
- ◆ Such limitations are unavoidable and make OTP not practical
 - ◆ why?

Now, what?

Our approach: Relax “perfectness”

Initial model

- ◆ the **perfect secrecy** (or security) requires that
 - ◆ the ciphertext **leaks absolutely no extra information** about the plaintext
 - ◆ to adversaries of **unlimited computational power**

Refined model

- ◆ a relaxed notion of security, called **computational security**, requires that
 - ◆ the ciphertext leaks **a tiny amount of extra information** about the plaintext
 - ◆ to adversaries with **bounded computational power**

Computational security

- ◆ to be contrasted against information-theoretic security
 - ◆ *de facto* way to model security in most settings
 - ◆ an integral part of modern cryptography w/ rigorous mathematical proofs
- ◆ entails two relaxations
 - ◆ security is guaranteed against **efficient** adversaries
 - ◆ if an attacker invests in **sufficiently large resources**, it may break security
 - ◆ goal: make required resources larger than those available to any realistic attacker!
 - ◆ security is guaranteed in a **probabilistic** manner
 - ◆ with some **small probability**, an attacker may break security
 - ◆ goal: make attack probability sufficiently small so that it can be practically ignored!

Towards a rigorous definition of computational security

Concrete approach

- ◆ “A scheme is (t, ε) -secure if any attacker A, running for time at most t , succeeds in breaking the scheme with probability at most ε ”

Asymptotic approach

- ◆ “A scheme is secure if any efficient attacker A succeeds in breaking the scheme with at most negligible probability”

Examples

- ◆ almost optimal security guarantees
 - ◆ if key length n , the number of possible keys is 2^n
 - ◆ attacker running for time t succeeds w/ prob. at most $\sim t/2^n$ (brute-force attack)
- ◆ if $n = 60$, security is enough for attackers running a desktop computer
 - ◆ 4 GHz (4×10^9 cycles/sec), checking all 2^{60} keys require about 9 years
 - ◆ if $n = 80$, a supercomputer would still need ~ 2 years
- ◆ today's recommended security parameter is at least $n = 128$
 - ◆ large difference between 2^{80} and 2^{128} ; e.g., #seconds since Big Bang is $\sim 2^{58}$
 - ◆ a once-in-100-years event corresponds to probability 2^{-30} of happening at a particular sec
 - ◆ if within 1 year of computation attack is successful w/ prob. $1/2^{60}$
then it is more likely that Alice and Bob are hit by lighting

Symmetric encryption, revisited: Security

Three equivalent “looks” of perfect secrecy

1) a posteriori = a priori

For every \mathcal{D}_M , $m \in M$ and $c \in C$, for which $\Pr [C = c] > 0$, it holds that

$$\Pr[M = m \mid C = c] = \Pr[M = m]$$

2) C is independent of M

For every $m, m' \in M$ and $c \in C$, it holds that

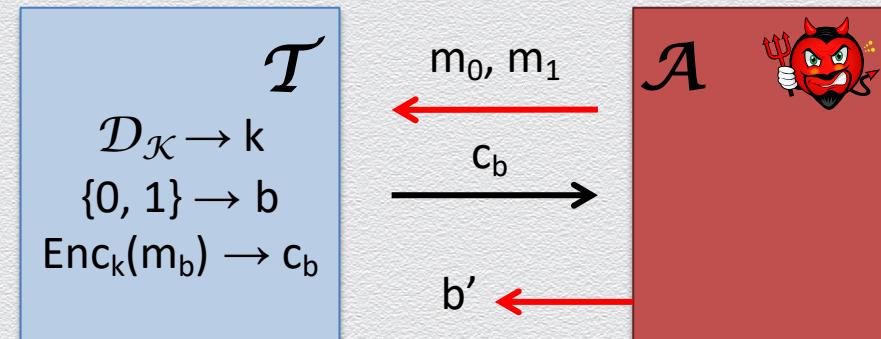

$$\Pr[\text{Enc}_k(m) = c] = \Pr[\text{Enc}_k(m') = c]$$

3) indistinguishability

For every \mathcal{A} , it holds that

$$\Pr[b' = b] = 1/2$$

 ciphertext looks **completely random**

Security relaxation

Perfect security: $M, \text{Enc}_K(M)$ are independent, **unconditionally**

- ◆ no extra information is leaked to any attacker

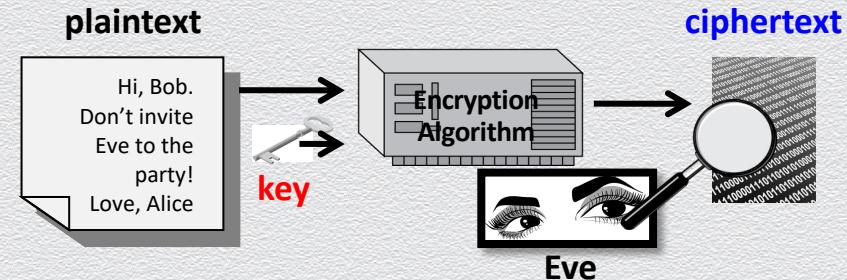

Computational security: $M, \text{Enc}_K(M)$ are independent, **for all practical purposes**

- ◆ no extra information is leaked **but a tiny amount**
 - ◆ e.g., with prob. 2^{-128} (or much less than the likelihood of being hit by lightning)
- ◆ to **computationally bounded** attackers
 - ◆ e.g., who cannot count to 2^{128} (or invest work of more than one century)
- ◆ attacker's best strategy remains **ineffective**
 - ◆ **random guess** a secret key or **exhaustive search** over key space (brute-force attack)

Recall: Main security properties against eavesdropping

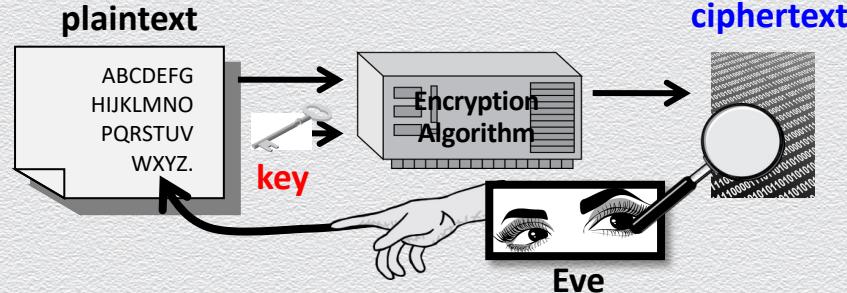

“plain”/EAV security

- ◆ protects against ciphertext-only attacks

“advanced”/CPA security

- ◆ protects against chosen plaintext attacks

Computational EAV-security or indistinguishability

Relax the definition of perfect secrecy that is based on indistinguishability

- ◆ require that target messages m_0, m_1 are chosen by a **PPT** attacker
- ◆ require that no such attacker can distinguish $\text{Enc}_k(m_0)$ from $\text{Enc}_k(m_1)$

non-negligibly better than guessing

PPT

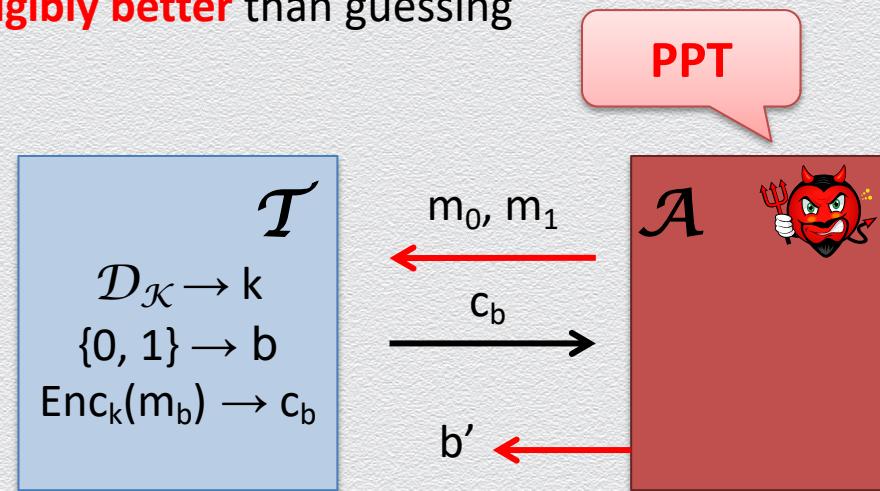

3) indistinguishability

For every \mathcal{A} , it holds that

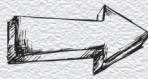

$$\Pr[b' = b] = 1/2 + \text{negligible}$$

PPT

something that can
be safely ignored

Computational CPA-security

Advanced security implies probabilistic encryption – why?

Strengthen the definition of computational plain-security

- ◆ allow attacker to have access to an **encryption “box”**
- ◆ allow the attacker to select m_0, m_1 **after** using this “box” (as many times as desired)

3) indistinguishability

For every PPT \mathcal{A} , it holds that

$$\Pr[b' = b] = 1/2 + \text{negligible}$$

PPT

something that can
be safely ignored
